1. Introduction

Numerical estimates for $\pi$ have been found in records of several ancient civilizations. These estimates were all based on inscribing and circumscribing regular polygons around a circle to get upper and lower bounds on the area (and thus upper and lower bounds on $\pi$ after dividing the area by the square of the radius). Such estimates are accurate to a few decimal places. Around 1600, Ludolph van Ceulen gave an estimate for $\pi$ to 35 decimal places. He spent many years of his life on this calculation, using a polygon with $2^{62}$ sides!

With the advent of calculus in the 17-th century, a new approach to the calculation of $\pi$ became available: infinite series. For instance, if we integrate

$$\frac{1}{1+t^2} = 1 - t^2 + t^4 - t^6 + t^8 - t^{10} + \ldots, \quad |t| < 1$$

from $t = 0$ to $t = x$ when $|x| < 1$, we find

$$\arctan x = x - \frac{x^3}{3} + \frac{x^5}{5} - \frac{x^7}{7} + \frac{x^9}{9} - \frac{x^{11}}{11} + \ldots.$$  

(1.1)

Actually, this is also correct at the boundary point $x = 1$. Since $\arctan 1 = \pi/4$, (1.1) specializes to the formula

$$\frac{\pi}{4} = 1 - \frac{1}{3} + \frac{1}{5} - \frac{1}{7} + \frac{1}{9} - \frac{1}{11} + \ldots,$$

(1.2)

which is due to Leibniz. It expresses $\pi$ in terms of an alternating sum of the reciprocals of the odd numbers. However, the series in (1.2) converges much too slowly to be of any numerical use. For example, truncating the series after 1000 terms and multiplying by 4 gives the approximation $\pi \approx 3.1405$, which is only good to two places after the decimal point.

There are other formulas for $\pi$ in terms of $\arctan$ values, such as

$$\frac{\pi}{4} = \arctan \left( \frac{1}{2} \right) + \arctan \left( \frac{1}{3} \right) = 2 \arctan \left( \frac{1}{3} \right) + \arctan \left( \frac{1}{7} \right) = 4 \arctan \left( \frac{1}{5} \right) - \arctan \left( \frac{1}{239} \right).$$

Since the series for $\arctan x$ is more rapidly convergent when $x$ is less than 1, these other series are more useful than (1.2) to get good numerical approximations to $\pi$. The last such calculation before the use of computers was by Shanks in 1873. He claimed to have found $\pi$ to 707 places. In the 1940s, the first computer estimate for $\pi$ revealed that Shanks made a mistake in the 528-th digit, so all his further calculations were in error!

Our interest here is not to ponder ever more elaborate methods of estimating $\pi$, but to prove something about the structure of this number: it is irrational. That is, $\pi$ is not the ratio of two integers. The basic idea is to argue by contradiction. We will show that if $\pi$ is rational, we run into a logical error. This is also the principle behind the proof that the simpler number $\sqrt{2}$ is irrational. However, there is an essential difference between the proof that $\sqrt{2}$ is irrational and the proof that $\pi$ is irrational. One can prove $\sqrt{2}$ is irrational using some simple algebraic manipulations with a hypothetical rational expression for $\sqrt{2}$ to reach a contradiction. But the irrationality of $\pi$ does not involve only algebra. It requires calculus.
Calculus can be used to prove irrationality of other numbers, such as \( e \) and rational powers of \( e \) (excluding of course \( e^0 = 1 \)).

The remaining sections are organized as follows. In Section 2, we prove \( \pi \) is irrational using some calculations with definite integrals. The irrationality of \( e \) is proved using infinite series in Section 3. A general discussion about irrationality proofs is in Section 4, and we apply those ideas to prove the irrationality of non-zero rational powers of \( e \) in Section 5.

2. Irrationality of \( \pi \)

The first serious theoretical result about \( \pi \) was established by Lambert in 1768: \( \pi \) is irrational. His proof involved an analytic device which is never met in calculus courses: infinite continued fractions. (A discussion of this work is in [1, pp. 68–78]. Lambert’s proof for \( \pi \) was actually a result about the tangent function. When \( r \) is a non-zero rational where the tangent function is defined, Lambert proved \( \tan r \) is irrational. Then, since \( \tan(\pi/4) = 1 \) is rational, \( \pi \) must be irrational or we get a contradiction.) The irrationality proof for \( \pi \) we give here is due to Niven [3] and uses integrals instead of continued fractions.

**Theorem 2.1.** The number \( \pi \) is irrational.

**Proof.** For any nice function \( f(x) \), a double integration by parts shows

\[
\int f(x) \sin x \, dx = -f(x) \cos x + f'(x) \sin x - \int f''(x) \sin x \, dx.
\]

Therefore (using \( \sin(0) = 0, \cos(0) = 1, \sin(\pi) = 0, \) and \( \cos(\pi) = -1 \)),

\[
\int_0^\pi f(x) \sin x \, dx = (f(0) + f(\pi)) - \int_0^\pi f''(x) \sin x \, dx.
\]

In particular, if \( f(x) \) is a polynomial of even degree, say \( 2n \), then repeating this calculation \( n \) times gives

\[
(2.1) \quad \int_0^\pi f(x) \sin x \, dx = F(0) + F(\pi),
\]

where \( F(x) = f(x) - f''(x) + f^{(4)}(x) - \cdots + (-1)^n f^{(2n)}(x) \).

To prove \( \pi \) is irrational, we will argue by contradiction. Assume \( \pi = p/q \) with non-zero integers \( p \) and \( q \). Of course, since \( \pi > 0 \) we can take \( p \) and \( q \) positive. We are going to apply (2.1) to a carefully (and mysteriously!) chosen polynomial \( f(x) \) and wind up constructing an integer which lies between 0 and 1. Of course no such integer exists, so we have a contradiction and therefore our hypothesis that \( \pi \) is rational is in error: \( \pi \) is irrational.

For any positive integer \( n \), set

\[
(2.2) \quad f_n(x) = q^n \frac{x^n(\pi - x)^n}{n!} = \frac{x^n(p - qx)^n}{n!}.
\]

This polynomial depends on \( n \) (and on \( \pi \)). We are going to apply (2.1) to this polynomial and find a contradiction when \( n \) becomes large.

But before working out the consequences of (2.1) for \( f(x) = f_n(x) \), we note the polynomial \( f_n(x) \) has two important properties:

- for \( 0 < x < \pi \), \( f_n(x) \) is positive and (when \( n \) is large) very small in absolute value,
- all the derivatives of \( f_n(x) \) at \( x = 0 \) and \( x = \pi \) are integers.
To show the first property is true, the positivity of $f_n(x)$ for $0 < x < \pi$ is immediate from its defining formula. To bound $|f_n(x)|$ from above when $0 < x < \pi$, note that $0 < \pi - x < \pi$, so $|x(\pi - x)| < \pi^2$. Therefore

$$|f_n(x)| \leq q^n \left( \frac{\pi^{2n}}{n!} \right) = \frac{(q\pi^2)^n}{n!}. \tag{2.3}$$

The upper bound tends to 0 as $n \to \infty$. In particular, the upper bound is less than 1 when $n$ gets sufficiently large.

To show the second property is true, we first look at $x = 0$. The coefficient of $x^j$ in $f_n(x)$ is $f_n^{(j)}(0)/j!$. At the same time, since $f_n(x) = x^n(p - qx)^n/n!$ and $p$ and $q$ are integers, the binomial theorem tells us the coefficient of $x^j$ can be written as $c_j/n!$ for some integer $c_j$. Therefore

$$f_n^{(j)}(0) = \frac{j!}{n!}c_j. \tag{2.4}$$

Since $f_n(x)$ has its lowest degree non-vanishing term in degree $n$, $c_j = 0$ for $j < n$, so $f_n^{(j)}(0) = 0$ for $j < n$. For $j \geq n$, $j!/n!$ is an integer, so $f_n^{(j)}(0)$ is an integer by (2.4).

To see the derivatives of $f_n(x)$ at $x = \pi$ are also integers, we use the identity $f_n(\pi-x) = f_n(x)$. Differentiate both sides $j$ times and set $x = 0$ to get $(-1)^j f_n^{(j)}(\pi) = f_n^{(j)}(0)$ for all $j$. Therefore, since the right side is an integer, the left side is an integer too. This concludes the proof of the two important properties of $f_n(x)$.

Now we look at (2.1) when $f = f_n$. Since all derivatives of $f_n$ at 0 and $\pi$ are integers, the right side of (2.1) is an integer when $f = f_n$ (look at the definition of $F(x)$). Therefore $\int_0^\pi f_n(x) \sin x \, dx$ is an integer for every $n$. Since $f_n(x)$ and $\sin x$ are positive on $(0, \pi)$, this integral is a positive integer. However, when $n$ is large, $|f_n(x) \sin x| \leq |f_n(x)| \leq (q\pi^2)^n/n!$ by (2.3). As $n \to \infty$, $(q\pi^2)^n/n! \to 0$. Therefore $\int_0^\pi f_n(x) \sin x \, dx$ is a positive integer less than 1 when $n$ is very large. This is absurd, so we have reached a contradiction. Thus $\pi$ is irrational. \hfill $\square$

This proof is quite puzzling. How did Niven know to choose those polynomials $f_n(x)$ or to compute that integral and make the estimate?

### 3. Irrationality of $e$

We turn now to a proof that $e$ is irrational. This was first established by Euler in 1737 using infinite continued fractions. We will prove the irrationality in a more direct manner, using infinite series. The idea of this proof is due to Fourier and it is short!

**Theorem 3.1.** The number $e$ is irrational.

**Proof.** Write

$$e = 1 + \frac{1}{2!} + \frac{1}{3!} + \cdots.$$ 

For any $n$,

$$e = \left(1 + \frac{1}{2!} + \frac{1}{3!} + \cdots + \frac{1}{n!}\right) + \left(\frac{1}{(n+1)!} + \frac{1}{(n+2)!} + \cdots\right)$$

$$= \left(1 + \frac{1}{2!} + \frac{1}{3!} + \cdots + \frac{1}{n!}\right) + \frac{1}{n!} \left(\frac{1}{n+1} + \frac{1}{(n+2)(n+1)} + \cdots\right).$$
The second term in parentheses is positive and bounded above by the geometric series
\[
\frac{1}{n+1} + \frac{1}{(n+1)^2} + \frac{1}{(n+1)^3} + \cdots = \frac{1}{n}.
\]
Therefore
\[
0 < e - \left(1 + \frac{1}{2!} + \frac{1}{3!} + \cdots + \frac{1}{n!}\right) \leq \frac{1}{n \cdot n!}.
\]
Write the sum \(1 + 1/2! + \cdots + 1/n!\) as a fraction with common denominator \(n!\), say as \(p_n/n!\). Clear the denominator \(n!\) to get
\[
(3.1) \quad 0 < n!e - p_n \leq \frac{1}{n}.
\]
So far everything we have done involves no unproved assumptions. Now we introduce the rationality assumption. If \(e\) is rational, then \(n!e\) is an integer when \(n\) is large (since any integer is a factor by \(n!\) for large \(n\)). But that makes \(n!e - p_n\) an integer located in the open interval (0, \(1/n\)), which is absurd. We have a contradiction, so \(e\) is irrational. \(\square\)

4. General Ideas

Now it’s time to think more systematically. The basic principle we need to understand is that numbers are irrational when they are approximated “too well” by rationals. Of course, any real number can be approximated arbitrarily closely by a suitable rational number: use a truncated decimal expansion. For instance, we can approximate \(\sqrt{2} = 1.41421356\ldots\) by
\[
(4.1) \quad \frac{14142}{10000} = 1.4142, \quad \frac{1414213}{1000000} = 1.414213.
\]
With truncated decimals, we achieve close estimates at the expense of rather large denominators. To see what this is all about, compare the above approximations with
\[
(4.2) \quad \frac{99}{70} = 1.41428571\ldots, \quad \frac{1393}{985} = 1.41421319\ldots,
\]
where we have achieved just as close an approximation with much smaller denominators (e.g., the second one is accurate to 6 decimal places with a denominator of only 3 digits). These rational approximations to \(\sqrt{2}\) are, in the sense of denominators, much better than the ones we find from decimal truncation.

To measure the “quality” of an approximation of a real number \(\alpha\) by a rational number \(p/q\), we should think not about the difference \(|\alpha - p/q|\) being small in an absolute sense, but about the difference being substantially smaller than \(1/q\) (thus tying the error with the size of the denominator in the approximation). In other words, we want
\[
q \left| \frac{\alpha - p}{q} \right| = |q\alpha - p|
\]
to be small in an absolute sense.

Measuring the approximation of \(\alpha\) by \(p/q\) using \(|q\alpha - p|\) rather than \(|\alpha - p/q|\) admittedly takes some time getting used to, if you are new to the idea. Consider what it says about our approximations to \(\sqrt{2}\). For example, from (4.1) we have
\[
|10000\sqrt{2} - 14142| = .135623, \quad |1000000\sqrt{2} - 1414213| = .562373,
\]
IRRATIONALITY OF $\pi$ AND $e$

and these are not small when measured against $1/10000 = .0001$ or $1/1000000 = .000001$. On the other hand, from the approximations to $\sqrt{2}$ in (4.2) we have

$$|70\sqrt{2} - 99| = .005050, \quad |985\sqrt{2} - 1393| = .000358,$$

which are small when measured against $1/70 = .014285$ and $1/985 = .001015$. We see vividly that $99/70$ and $1393/985$ really should be judged as “good” rational approximations to $\sqrt{2}$ while the decimal truncations are “bad” rational approximations to $\sqrt{2}$.

The importance of this point of view is that it gives us a general strategy for proving numbers are irrational, as follows.

**Theorem 4.1.** Let $\alpha \in \mathbb{R}$. If there is a sequence of integers $p_n, q_n$ such that $q_n\alpha - p_n \neq 0$ and $|q_n\alpha - p_n| \to 0$ as $n \to \infty$, then $\alpha$ is irrational.

In other words, if $\alpha$ admits a “very good” sequence of rational approximations, then $\alpha$ must be irrational.

**Proof.** Since $0 < |q_n\alpha - p_n| < 1$ for large $n$, by hypothesis, we must have $q_n \neq 0$ for large $n$. Therefore, since only large $n$ is what matters, we may change terms at the start and assume $q_n \neq 0$ for all $n$.

To prove $\alpha$ is irrational, suppose it is rational: $\alpha = a/b$, where $a$ and $b$ are integers (with $b \neq 0$). Then

$$|\alpha - p_n/q_n| = \frac{|a/b - p_n/q_n|}{bq_n} = \frac{|q_n a - p_n b|}{bq_n}.$$

Clearing the denominator $q_n$,

$$|q_n \alpha - p_n| = \frac{|q_n a - p_n b|}{b}.$$

Since this is not zero, the integer $q_n a - p_n b$ is non-zero. Therefore $|q_n a - p_n b| \geq 1$, so

$$|q_n \alpha - p_n| \geq \frac{1}{b}.$$ 

This lower bound contradicts $|q_n \alpha - p_n|$ tending to 0. \qed

It turns out the condition in Theorem 4.1 is not just sufficient to prove irrationality, but it is also necessary: if $\alpha$ is irrational then there is such a sequence of integers $p_n, q_n$ (whose ratios provide good rational approximations to $\alpha$). A proof can be found in [2, p. 277]. We will not have any need for the necessity (except maybe for its psychological boost) and therefore omit the proof.

Of course, to use Theorem 4.1 to prove irrationality of a number $\alpha$ we need to find the integers $p_n$ and $q_n$. For the number $e$, these integers can be found directly from truncations to the infinite series for $e$, as we saw in (3.1). In other words, rather than saying $e$ is irrational because the proof of Theorem 3.1 shows in the end that rationality of $e$ leads to an integer between 0 and 1, we can say $e$ is irrational because the proof of Theorem 3.1 exhibits a sequence of good rational approximations to $e$. In other words, the proof of Theorem 3.1 can stop at (3.1) and then appeal to Theorem 4.1.

While other powers of $e$ are also irrational, it is not feasible to prove their irrationality by adapting the proof of Theorem 3.1. For instance, what happens if we try to prove $e^2$ is irrational from taking truncations of the infinite series $e^2 = \sum_{k=0}^{\infty} 2^k/k!$? Writing the truncated sum $\sum_{k=0}^{n} 2^k/k!$ in reduced form as, say, $a_n/b_n$, numerical data suggest $b_n e^2 - a_n$
does not tend to 0. (As numerical evidence, the value of $b_n e^2 - a_n$ at $n = 22, 23, 24$ is roughly .0026, 1.4488, and .3465. Since the corresponding values of $b_n$ have 12, 16, and 17 decimal digits, these differences are not small by comparison with $1/b_n$, so the approximations $a_n / b_n$ to $e^2$ are not that good.) Thus, these rational approximations to $e^2$ probably won’t fit the conditions of Theorem 4.1 to let us prove the irrationality of $e^2$.

5. IRRATIONALITY OF RATIONAL POWERS OF $e$

We want to use Theorem 4.1 to prove the following generalization of the irrationality of $e$.

**Theorem 5.1.** For any integer $a \neq 0$, $e^a$ is irrational.

To find good rational approximations for a particular power of $e$ (good enough, that is, to establish irrationality), we will not use a particular series expansion, but rather use the interaction between the exponential function $e^x$ and integration. Some of the mysterious ideas from Niven’s proof of the irrationality of $\pi$ will show up in this context.

Before we prove Theorem 5.1, we note two immediate corollaries.

**Corollary 5.2.** When $r$ is a non-zero rational number, $e^r$ is irrational.

*Proof.* Write $r = a/b$ with non-zero integers $a$ and $b$. If $e^r$ is rational, so is $(e^r)^b = e^a$, but this contradicts Theorem 5.1. Therefore $e^r$ is irrational. $\square$

**Corollary 5.3.** For any positive rational number $r \neq 1$, $\ln r$ is irrational.

*Proof.* The number $\ln r$ is non-zero. If $\ln r$ is rational, then Corollary 5.2 tells us $e^{\ln r}$ is irrational. But $e^{\ln r} = r$ is rational. We have a contradiction, so $\ln r$ is irrational. $\square$

The proof of Theorem 5.1 will use the following lemma, which tells us how to integrate $e^{-x} f(x)$ when $f(x)$ is any polynomial.

**Lemma 5.4** (Hermite). Let $f(x)$ be a polynomial of degree $m \geq 0$. For any number $a$,

$$\int_0^a e^{-x} f(x) \, dx = \sum_{j=0}^m f^{(j)}(0) - e^{-a} \sum_{j=0}^m f^{(j)}(a).$$

*Proof.* We compute $\int e^{-x} f(x) \, dx$ by integration by parts, taking $u = f(x)$ and $dv = e^{-x} \, dx$. Then $du = f'(x) \, dx$ and $v = -e^{-x}$, so

$$\int e^{-x} f(x) \, dx = -e^{-x} f(x) + \int e^{-x} f'(x) \, dx.$$ 

Repeating this process on the new indefinite integral, we eventually obtain

$$\int e^{-x} f(x) \, dx = -e^{-x} \sum_{j=0}^m f^{(j)}(x).$$

Now evaluate the right side at $x = a$ and $x = 0$ and subtract. $\square$

**Remark 5.5.** It is interesting to make a special case of this lemma explicit. When $f(x) = x^n$ ($n$ a positive integer), the lemma says

$$\int_0^a e^{-x} x^n \, dx = n! - \frac{1}{e^a} \sum_{j=0}^n n(n-1) \cdots (n-j+1) a^{n-j}.$$
Letting \(a \to \infty\) (\(n\) is fixed), the second term on the right tends to 0, so \(\int_0^\infty e^{-x^n} \, dx = n!\). This integral formula for \(n!\) is due to Euler.

Now we prove Theorem 5.1.

**Proof.** We rewrite Hermite’s lemma by multiplying through by \(e^a\):

\[
e^a \int_0^a e^{-x} f(x) \, dx = e^a \sum_{j=0}^m f^{(j)}(0) - \sum_{j=0}^m f^{(j)}(a).
\]

Equation (5.1) is valid for any number \(a\) and any polynomial \(f(x)\). Let \(a\) be a non-zero integer at which \(e^a\) is assumed to be rational. We want to use for \(f(x)\) a polynomial (actually, a sequence of polynomials \(f_n(x)\)) with two properties:

- the left side of (5.1) is non-zero and (when \(n\) is large) very small in absolute value,
- all the derivatives of the polynomial at \(x = 0\) and \(x = a\) are integers.

Then the right side of (5.1) will have the properties of the differences \(q_n \alpha - p_n\) in Theorem 4.1, with \(\alpha = e^a\) and the two sums on the right side of (5.1) being \(p_n\) and \(q_n\).

Our choice of \(f(x)\) is

\[
f_n(x) = \frac{x^n(x-a)^n}{n!}
\]

where \(n \geq 1\) is to be determined. (Note the similarity with (2.2) in the proof of the irrationality of \(\pi!\)) In other words, we consider the equation

\[
e^a \int_0^a e^{-x} f_n(x) \, dx = e^a \sum_{j=0}^{2n} f_n^{(j)}(0) - \sum_{j=0}^{2n} f_n^{(j)}(a).
\]

We can see (5.3) is non-zero by looking at the left side. The number \(a\) is non-zero and the integrand \(e^{-x} f_n(x) = e^{-x} x^n (x-a)^n/n!\) on the interval \((0,a)\) has constant sign, so the integral is non-zero. Now we estimate the size of (5.3) by estimating the integral on the left side. Since

\[
\int_0^a e^{-x} f_n(x) \, dx = a^{2n+1} \int_0^1 e^{-ay} y^n (y-1)^n \frac{n!}{n!} \, dy,
\]

we can bound the left side of (5.3) from above:

\[
\left| e^a \int_0^a e^{-x} f_n(x) \, dx \right| \leq \frac{e^a |a|^{2n+1}}{n!} \int_0^1 e^{-ay} \, dy.
\]

As a function of \(n\), this upper bound is a constant times \((|a|^2)^n/n!\). As \(n \to \infty\), this bound tends to 0.

To see that, for any \(n \geq 1\), the derivatives \(f_n^{(j)}(0)\) and \(f_n^{(j)}(a)\) are integers for every \(j \geq 0\), first note that the equation \(f_n(a-x) = f_n(x)\) tells us after repeated differentiation that \((-1)^j f_n^{(j)}(a) = f_n^{(j)}(0)\). Therefore it suffices to show all the derivatives of \(f_n(x)\) at \(x = 0\) are integers. The proof that all \(f_n^{(j)}(0)\) are integers is just like that in the proof of Theorem 2.1, so the details are left to the reader to check. (The general principle is this: for any polynomial \(g(x)\) which has integer coefficients and is divisible by \(x^n\), all derivatives of \(g(x)/n!\) at \(x = 0\) are integers.)

The first property of the \(f_n\)’s tells us that \(|q_n e^a - p_n|\) is positive and tends to 0 as \(n \to \infty\). The second property of the \(f_n\)’s tells us that the sums \(p_n = \sum_{j=0}^{2n} f_n^{(j)}(a)\) and \(q_n = \sum_{j=0}^{2n} f_n^{(j)}(0)\)
\[ \sum_{j=0}^{2n} f_n^{(j)}(a) \] on the right side of (5.3) are integers. Therefore the hypotheses of Theorem 4.1 are met, so \( e^a \) is irrational.

\[ \square \]

What really happened in this proof? We actually wrote down some very good rational approximations to \( e^a \). They came from values of the polynomial

\[ F_n(x) = \sum_{j=0}^{2n} f_n^{(j)}(x). \]

Indeed, Theorem 5.1 tells us \( F_n(a)/F_n(0) \) is a “good” rational approximation to \( e^a \) when \( n \) is large. (The dependence of \( F_n(x) \) on \( a \) is hidden in the formula for \( f_n(x) \).) The following table illustrates this for \( a = 2 \), where the entry at \( n = 1 \) is pretty bad since \( F_1(0) = 0 \).

| \( n \) | \( |F_n(0)e^x - F_n(2)| \) |
|-------|------------------|
| 1     | 4                |
| 2     | 1.5562           |
| 3     | .43775           |
| 4     | .09631           |
| 5     | .01739           |
| 6     | .00266           |
| 7     | .00035           |
| 8     | .00004           |

If we take \( a = 1 \), the rational approximations we get for \( e^a = e \) by this method are different from the partial sums \( \sum_{k=0}^{n} 1/k! \).

Although the proofs of Theorems 2.1 and 5.1 are similar in the sense that both used estimates on integrals, the proof of Theorem 2.1 did not show \( \pi \) is irrational by exhibiting a sequence of good rational approximations to \( \pi \). The proof of Theorem 2.1 was an “integer between 0 and 1” proof by contradiction. No good rational approximations to \( \pi \) were produced in that proof. It is simply harder to get our grips on \( \pi \) than it is on powers of \( e \).

REFERENCES
